(Received 20 December 1982)

With the extension of the work of the preceding paper, the relativistic front form for Maxwell’s equations for electromagnetism is developed and shown to be particularly suited to the description of paraxial waves. The generators of the Poincaré group in a form applicable directly to the electric and magnetic field vectors are derived. It is shown that the effect of a thin lens on a paraxial electromagnetic wave is given by a six-dimensional transformation matrix, constructed out of certain special generators of the Poincaré group. The method of construction guarantees that the free propagation of such waves as well as their transmission through ideal optical systems can be described in terms of the metaplectic group, exactly as found for scalar waves by Bacy and Cadilhac. An alternative formulation in terms of a vector potential is also constructed. It is chosen in a gauge suggested by the front form and by the requirement that the lens transformation matrix act locally in space. Pencils of light with accompanying polarization are defined for statistical states in terms of the two-point correlation function of the vector potential. Their propagation and transmission through lenses are briefly considered in the paraxial limit. This paper extends Fourier optics and completes it by formulating it for the Maxwell field. We stress that the derivations depend explicitly on the “homonochromatic” idealization as well as the identification of the ideal lens with a quadratic phase shift and are heuristic to this extent.

I. INTRODUCTION

In the preceding paper (hereafter referred to as I) we have set up a general formalism, based on the front form of relativistic dynamics, for the treatment of paraxial-wave propagation problems in optics. The treatment was restricted to the case of scalar waves for simplicity, and we analyzed in detail the group-theoretical basis underlying the front form and the paraxial limit. It was shown that both the free propagation of such waves and their passage through ideal optical systems was very similar in mathematical structure to the quantum mechanics of free nonrelativistic particles in two dimensions encountering harmonic impulses. Moreover, the significance of the metaplectic group for this class of problems, first realized in the work of Bacy and Cadilhac, was traced back to the structure of the Poincaré group: It arises from the fact that in the Lie algebra of the Poincaré group there is a subalgebra isomorphic to a central extension of the two-dimensional Galilei algebra, and this is exposed by the front form. We also analyzed the behavior of generalized light rays in this context and presented their extremely simple free propagation behavior as well as their passage through ideal lenses.

The present paper extends this work to the complete electromagnetic field described by Maxwell’s equations, so that a satisfactory account of polarization in paraxial wave problems can be given. Since in I we have explained in considerable detail how the front form description of wave propagation is related to the more familiar one employing separate space and time coordinates, we shall emphasize in this paper just those features that are particularly associated with the Maxwell system. We shall extend the group theoretical discussion given in I to determine the effect of ideal optical systems on Maxwellian waves, and we shall find that this procedure gives physically correct results. Thus the relevance of the metaplectic group carries over to vector waves.

We use the same metric conventions and terminology for the Poincaré group as in I. Section II puts the Maxwell equations into the front form, pointing out that in contrast to the instant form there are now equal numbers of constraint conditions and dynamical equations. The generators of the Poincaré group, in a form suitable for application to the six independent components of the Maxwell field tensor, are worked out. Paraxial solutions to Maxwell’s equations are described in Sec. III. It is a very useful feature of the front form that it shows one how to rearrange the field components in particular combinations and in a specific sequence, which makes the description of paraxial waves most natural. The action of a lens on such waves is determined by the principle that in the lens transformation function of scalar wave theory, the role of the transverse position coordinates must now be played by the conjugates to transverse momentum provided by the Galilean subalgebra of the Poincaré algebra. For vector waves described in terms of the six field strengths \( \vec{E}, \vec{B} \), each thin lens is then represented by a corresponding transformation matrix, rather than by a function, of dimension six. For the simplest case of an axially sym-
metric lens this matrix is explicitly computed, and it is shown that its action on an incident wave gives physically expected results. In Sec. IV we give a treatment based on the vector potential, leading to simpler matrix algebra. We describe a new gauge associated with the front form and particularly suited to paraxial waves, and calculate the lens transformation matrix, now three dimensional, again for the axially symmetric case. It is verified that the treatments of Secs. III and IV give mutually consistent results. In Sec. V we show how to define generalized rays of light with polarization properties, in terms of the two-point correlation tensors of the electromagnetic field. Their free propagation and passage through thin lenses is briefly described, always working within the paraxial approximation. Finally we summarize our work in Sec. VI, and especially provide a simple reason for the correctness of our principle based on the underlying group theory.

II. MAXWELL’S EQUATIONS IN THE FRONT FORM

The free Maxwell equations in conventional three-dimensional notation appropriate to the instant form are

\[ \partial_\sigma \mathbf{E} - \nabla \times \mathbf{B} = 0, \]

\[ \partial_\tau \mathbf{B} + \nabla \times \mathbf{E} = 0, \]

\[ \nabla \cdot \mathbf{E} = 0, \]

\[ \nabla \cdot \mathbf{B} = 0. \]

(2.1a)

(2.1b)

(2.1c)

(2.1d)

In (2.1a) and (2.1b) we have genuine equations of motion for \( \mathbf{E} \) and \( \mathbf{B} \); (2.1c) and (2.1d) are two constraint equations to be obeyed at each time. Of course, the former ensure that the latter are maintained in time. If a conserved external current \( j^\mu \) is included as a source, the equation of motion (2.1a) and the constraint (2.1c) acquire \( -j^\tau \) and \( j^0 \), respectively, on their right-hand sides, while (2.1b) and (2.1d) are unchanged. As parts of a relativistic covariant antisymmetric tensor field \( F_{\mu\nu} \), we identify \( \mathbf{E} \) and \( \mathbf{B} \) by

\[ E_j = F_{j0}, \quad B_\tau = \frac{1}{2} \epsilon_{\mu\nu\lambda} F_{\mu\lambda}. \]

(2.2)

To express these equations in the front form, we need a set of conventions for defining new components of vectors and tensors. Just as the space-time coordinates \( x^0, x^1 \) are replaced by the combinations \( \tau = \frac{1}{2}(x^0 + x^1) \) and \( \sigma = x^0 - x^1 \), for any contravariant vector \( X^\mu \) we define

\[ X^\tau = \frac{1}{2}(X^0 + X^1), \quad X^\sigma = X^0 - X^1. \]

(2.3)

Similarly for a covariant vector \( Y_\mu \) we define

\[ Y_\sigma = \frac{1}{2}(Y_0 - Y_1), \quad Y_\tau = Y_0 + Y_1, \]

(2.4)

so that the invariant takes the form (indices \( a,b,\ldots \), take values \( 1,2 \))

\[ X^\mu Y_\mu = X_0 Y_0 + X_1 Y_1 = X_2 Y_2 + X_3 Y_3 + X_4 Y_4 + X_5 Y_5. \]

(2.5)

The accompanying form of the metric and the rules for raising and lowering indices \( \sigma, \tau \) are

\[ g_{ab} = \delta_{ab}, \quad g_{\sigma\tau} = g_{\tau\sigma} = -1, \]

(2.6a)

\[ X^\sigma = -X_\tau, \quad X^\tau = -X_\sigma, \quad X^a = X_a. \]

(2.6b)

Partial derivatives with respect to \( \sigma \) and \( \tau \) are

\[ \partial_\sigma = \frac{\partial}{\partial \sigma} = \frac{1}{2}(\partial_0 - \partial_1), \quad \partial_\tau = \frac{\partial}{\partial \tau} = \partial_0 + \partial_1. \]

(2.7)

Consistent with Eq. (2.6a) we have \( \partial^\sigma = -\partial^\tau \partial^\sigma = -\partial_\tau \).

We now introduce combinations \( U_a, V_\alpha \) of the transverse components \( E_a, B_\alpha \) in the following way:

\[ U_a = F_{a\sigma} = -\frac{1}{2}(E_a + \epsilon_{ab} B_b), \]

(2.8a)

\[ V_\alpha = F_{a\tau} = -(E_a - \epsilon_{ab} B_b). \]

(2.8b)

The remaining two components \( E_3, B_3 \) are carried along unchanged, noting only that

\[ E_3 = F_{3\tau}, \quad B_3 = \frac{1}{2} \epsilon_{ab} F_{3b}. \]

(2.9)

From these definitions we can see that in the front form \( (B_3, U_a) \) form a natural “magnetic” triplet of field components, while \( (E_3, V_\alpha) \) form an “electric” triplet. Note that the components \( U_a \) are defined in terms of \( F_{\mu\nu} \) in the same way in which the Galilean generators \( G_a \) are defined starting with the homogeneous Lorentz generators \( M_{\mu\nu} \), since \( G_3 = M_{3\sigma} \). We will see in the next section that the sets of field components \( U_a, E_3 \) and \( B_3, V_\alpha \) are very well suited to describe paraxial waves.

With these definitions it is straightforward to rewrite all the Maxwell equations in the front variables. We now find that there are four equations of motion specifying the \( \tau \) derivatives of certain field components, and four constraint equations:

\[ \partial_\sigma E_3 = \partial_\sigma V_\alpha, \]

(2.10a)

\[ \partial_\tau U_a = \epsilon_{ab} \partial_\sigma V_b, \]

(2.10b)

\[ \partial_\sigma U_a = -\frac{1}{2}(\partial_\sigma E_3 + \epsilon_{ab} \partial_\tau E_3), \]

(2.10c)

\[ \partial_\sigma E_3 = -\partial_\tau U_a, \]

(2.10d)

\[ \partial_\tau B_3 = \epsilon_{ab} \partial_\sigma U_b, \]

(2.10e)

\[ \partial_\sigma V_\alpha = -\frac{1}{2}(\partial_\sigma E_3 - \epsilon_{ab} \partial_\tau E_3). \]

(2.10f)

As for the maintenance of the constraints in \( \tau \), we find that (2.10f) together with the equations of motion (2.10a)–(2.10c) ensures this for (2.10d) and (2.10e); while (2.10f) itself is maintained because of the wave equation for \( V_\alpha \).

Let us now compute the generators of the Poincaré group suitable for action on the field tensor \( F_{\mu\nu} \). Under the infinitesimal Poincaré transformation

\[ x^\mu \rightarrow x'^\mu = x^\mu + \omega^\mu \nu x_\nu + a^\mu, \]

(2.11)

the geometrical transformation rule for \( F_{\mu\nu} \) is

\[ F'_{\mu\nu}(x') = F_{\mu\nu}(x) + \omega_{\mu}^{\lambda} F_{\lambda\nu}(x) - \omega_{\nu}^{\lambda} F_{\mu\lambda}(x). \]

(2.12)

This means that the change in functional form in \( F_{\mu\nu} \) is of amount

\[ \delta F_{\mu\nu}(x) = - (\omega_{\mu}^{ab} x_{\mu} + a^{\sigma}) \partial_\sigma F_{\mu\nu}(x) + \omega_{\mu}^{\lambda} F_{\lambda\nu}(x) - \omega_{\nu}^{\lambda} F_{\mu\lambda}(x). \]

(2.13)

In I we set up a generator \( G \) to accompany the transformation (2.11) (Ref. 8):

\[ G = \frac{1}{2} \epsilon_{\mu\nu\rho} M_{\mu\nu} - a^\mu P_\mu \]

(2.14)
The basic generators $M_{\mu\nu}P_{\mu}$ must now be determined in such a way that on applying $i\partial$ to $F_{\mu\nu}$ we get just the change $\delta F_{\mu\nu}$ of Eq. (2.13). To be specific, let us arrange the components $\vec{E}, \vec{B}$ of $F_{\mu\nu}$ into a six-component column vector $\left(\vec{g}^0\right)$. Then each of the generators $M_{\mu\nu}P_{\mu}$ is simultaneously a differential operator on space-time variables and a six-dimensional matrix. Wherever the unit matrix in six dimensions is to appear we do not explicitly indicate it but let it be understood. Then the various generators are

$$P_{\mu} = -i\partial_{\mu},$$

$$\vec{J} = -i\vec{x} \times \vec{\nabla} + \begin{bmatrix} \vec{S} & 0 \\ 0 & \vec{S} \end{bmatrix},$$

$$\vec{K} = i(x^0\vec{\nabla} + \vec{x} \partial_0) + \begin{bmatrix} 0 & \vec{S} \\ -\vec{S} & 0 \end{bmatrix}. \tag{2.15}$$

Here $\vec{S}$ denotes the triplet of Hermitian three-dimensional spin-1 matrices taken in the Cartesian form, i.e.,

$$(S_j)_{kl} = -ie_{jkl}. \tag{2.16}$$

It is a straightforward matter to rewrite these generators $M_{\mu\nu}P_{\mu}$ suitable for application to a column vector in which one lists the components of $F_{\mu\nu}$ in the sequence, say, $U_0, E_3, B_3, V_3$, but we shall leave them in the above form.

For determining the effect of a thin lens on an incident paraxial wave we recall from I that the particular generators $G_0 = M_{\sigma \alpha}$ are needed. They can be easily found from Eq. (2.15) and are

$$G_0 = M_{\sigma \alpha} - \tau P_{\sigma} + G_{\sigma}^{(spin)},$$

$$G_{1}^{(spin)} = \frac{1}{2} \begin{bmatrix} -S_2 & S_1 \\ -S_1 & -S_2 \end{bmatrix},$$

$$G_{2}^{(spin)} = \frac{1}{2} \begin{bmatrix} S_1 & S_2 \\ -S_2 & S_1 \end{bmatrix},$$

$$M = \frac{1}{2} (P^0 + P^3) = i\partial_{\tau}. \tag{2.17}$$

We shall use these generators and explore their properties in the next section.

### III. PARAXIAL SOLUTIONS AND THE LENS TRANSFORMATION

We saw in I for the scalar case that since we are dealing with waves traveling precisely with the speed of light, there is a class of solutions of the wave equation that cannot be described in the format of an initial value problem with respect to the front label $\tau$. These are antiaxial waves depending on $\tau$ alone but not on $\sigma$ and $x_\alpha$. For the Maxwell system (2.10), these solutions are

$$U_\alpha = E_3 = B_3 = 0, \quad V_\alpha(\sigma;x_\alpha;\tau) = f_\alpha(\tau), \quad \tag{3.1}$$

with the two functions $f_\alpha(\tau)$ arbitrary. In wave-number space such solutions involve only wave vectors for which $k^0 = -k^3$, $k_0 = 0$, and on these the mass operator $M$ of the two-dimensional Galilei group vanishes identically. Out of the seven generators of the Poincaré group associated with transformations leaving the front invariant, $G_0, P_\sigma$, and $M$ annihilate each solution of the type (3.1), while $J_3$ and $K_3 = \tau(P^0 - P^3)$ rotate and scale it, respectively. As in I, we will here exclude such solutions from consideration.

We turn now to setting up a convenient description of paraxial solutions of Eqs. (2.10), corresponding to waves propagating roughly along the positive $x^3$ axis. We are interested only in analytic signal solutions, and the terms quasishenochromatic, henochromatic, paraxial, etc., will be used in the same sense as in I. An exactly axial wave has vanishing $E_3, B_3, V_3$ while each $U_\alpha$ is an arbitrary function of $\sigma$; so this is a $\tau$-independent solution. One therefore expects that for the paraxial case the important components of the field are $U_0$, while $E_3, B_3$, and $V_3$ will be smaller in comparison. A quasishenochromatic paraxial wave will involve a mean value $\langle \mathcal{M} \rangle_0$ and a spread $\Delta \mathcal{M}$ in values of $\mathcal{M}$, and a range of values $|k_1| \leq \Delta k$ of the transverse wave vector, which will obey as in I the conditions

$$\Delta \mathcal{M} \ll \mathcal{M}_0, \quad \Delta k \ll \mathcal{M}_0. \tag{3.2}$$

In the region of space-time where $\sigma$ and $\tau$ obey

$$|\sigma| \ll \frac{2\pi}{\mathcal{M}_0 \Delta \mathcal{M}}, \tag{3.3}$$

$$|\tau| \ll \frac{4\pi}{\mathcal{M}_0 \Delta \mathcal{M}} \left[\frac{-\mathcal{M}_0}{\Delta \mathcal{M}}\right]^2,$$

all components of the field will be henochromatic to good approximation. For $U_\alpha$ in this region we assume the forms

$$U_\alpha(\sigma;x_\alpha;\tau) \approx e^{-i\cdot \cdot \cdot} \int d^2k_1f_\alpha(k_1)\exp\left[i\left(k_1 \cdot x_\alpha - k_1^2 \tau/2\mathcal{M}_0\right)\right], \tag{3.4}$$

where the two functions $f_\alpha(k_1)$ are nonzero only for $|k_1| \leq \Delta k$. From the constraint equations (2.10d)–(2.10f) we are able to determine all the other field components in the region (3.3) directly in terms of $U_\alpha$:

$$E_3(\sigma;x_\alpha;\tau) \approx \frac{e^{-i\cdot \cdot \cdot}}{-\mathcal{M}_0}\int d^2k_1k_2f_\alpha(k_1)\exp\left[i\left(k_1 \cdot x_\alpha - k_1^2 \tau/(2\mathcal{M}_0)\right)\right],$$

$$B_3(\sigma;x_\alpha;\tau) \approx -\frac{e^{-i\cdot \cdot \cdot}}{-\mathcal{M}_0}\int d^2k_1\epsilon_{\alpha\beta\gamma}k_2f_\alpha(k_1)\exp\left[i\left(k_1 \cdot x_\alpha - k_1^2 \tau/(2\mathcal{M}_0)\right)\right],$$

$$V_\alpha(\sigma;x_\alpha;\tau) \approx -\frac{e^{-i\cdot \cdot \cdot}}{2\mathcal{M}_0}\int d^2k_1[(k_1^2_1 - k_1^2)\mathcal{P}_3 + 2k_1k_2\mathcal{P}_1]f_\alpha(k_1)\exp\left[i\left(k_1 \cdot x_\alpha - k_1^2 \tau/(2\mathcal{M}_0)\right)\right]. \tag{3.5}$$
To simplify the expressions for $V_a$ we have used a pair of Pauli matrices $\rho_1$ and $\rho_2$. One can now check that the remaining Maxwell equations, the true equations of motion (2.10a)—(2.10c) in the front form, are all obeyed by the expressions (3.4) and (3.5), with no conditions arising on $f_a(k).$

The paraxial nature of the wave is determined by the ratio $\Delta k/\kappa$, which is assumed to be a very small number. Viewing this as a controlling parameter we see that in the enochromatic case the field components $E_3, B_3$ are 1 order of magnitude smaller than $U_a$, while $V_a$ are 2 orders of magnitude smaller:

$$E_3, B_3 \sim \frac{\Delta k}{\kappa_0} U_a, \quad V_a \sim \left(\frac{\Delta k}{\kappa_0}\right)^2 U_a. \quad (3.6)$$

In addition each individual field component depends most strongly on $\sigma$, relatively weakly by the factor $\Delta k/\kappa_0$ on $x_1$, and even more weakly by the factor $(\Delta k/\kappa_0)^2$ on $\tau$. From (3.6) we can say that in the paraxial region the equality

$$E_a \approx \epsilon_{ab} B_b \approx -U_a \quad (3.7)$$

is good up to and including first-order terms in $\Delta k/\kappa_0$. The evolution of each component of the field in $\tau$ is given by a Schrödinger-type equation:

$$i \frac{\partial}{\partial \tau}(U_a, E_3, B_3, V_a) = \frac{-P_a P_a}{2\kappa_0} (U_a, E_3, B_3, V_a). \quad (3.8)$$

We shall now calculate, to lowest nontrivial order, the effect of a thin circular lens of focal length $f$ on a quasienochromatic paraxial electromagnetic wave incident on it from the left. The lens will be assumed to be placed centrally on and normally to the axis. This calculation will be based on the idea that the relevance of the metaplectic group for such problems, disclosed by the work of Bacry and Cadilhac for scalar waves, must be maintained in a natural way for vector waves. The way to achieve this has been recognized already in I. After writing the generators of the Poincaré group for the Maxwell case in the form suited to the front variables, one isolates the $(2+1)$-dimensional Galilean subalgebra. This subalgebra supplies us with canonical conjugates $G_a/\kappa_0$ to the transverse "momenta" $P_a$. We now use these in place of the transverse position coordinates $x_a$ in the lens transformation law for scalar waves described in I. We need to assume as in I that the wave is such that the parameters $\kappa_0, \Delta \kappa, \Delta k$ obey

$$\Delta k / \kappa_0 \leq 2 \left(\frac{\Delta \kappa}{\kappa_0}\right)^{1/2}. \quad (3.9)$$

This will permit us to say, when Eqs. (3.3) hold, that a lens located in ordinary space at, say, $x^3=0$, can be thought of to good approximation as being "located" at $\tau=0$ in the front language.

For a scalar paraxial wave incident on the lens, the effect of the lens is to introduce a phase factor

$$e^{i\varphi(x_1)}, \quad \varphi(x_1) = \frac{\kappa_0}{\kappa_0}(n\Delta_0 - x_1^2/2f). \quad (3.10)$$

Here, $n$ and $\Delta_0$ are the refractive index and lens thickness, respectively, and it is understood as part of the paraxial approximation that this expression for $\varphi$ must be used only for $|x_1| << f$. From Eq. (2.17) on setting $\tau=0$ we get the analog of $x_a$ for the Maxwell case:

$$x_a / M = x_a + \frac{1}{M} G_{a}^{(spin)} \approx x_a + \frac{1}{\kappa_0} G_{a}^{(spin)}. \quad (3.11)$$

We are therefore led to suggest that when a paraxial Maxwell wave encounters the lens, the effect will be described by a lens phase transformation matrix

$$\Omega(x_1) = \exp \left(-\frac{i}{2f} \frac{\kappa_0}{2f} \left( x_1 + \frac{1}{\kappa_0} G_{a}^{(spin)} \right)^2 \right), \quad (3.12)$$

where a constant inessential phase has been omitted. We now evaluate this matrix: The algebraic properties of $G_{a}^{(spin)}$ allow us to do so exactly.

Let us introduce a set of auxiliary Pauli matrices $\rho_1, \rho_2, \rho_3$ such that

$$\rho_1^2 = \rho_2^2 = \rho_3^2 = 1, \quad \rho_1 \rho_2 = -\rho_2 \rho_1,$$

e etc. We may then write the six-dimensional matrices $G_{a}^{(spin)}$ as Kronecker products of $\rho$'s and $S$'s in this way:

$$G_{1}^{(spin)} = \frac{1}{2}(i\rho_2 S_1 - S_2), \quad (3.13)$$

$$G_{2}^{(spin)} = \frac{1}{2}(iS_1 + i\rho_2 S_2).$$

From here we see that

$$G_{2}^{(spin)} = -i\rho_2 G_{1}^{(spin)}. \quad (3.14)$$

It is obvious that $G_{1}^{(spin)}$ and $G_{2}^{(spin)}$ commute. This is consistent with their being parts of the commuting Galilean boost generators. Moreover, since $S_j$ are the generators of the spin-1 representation of the rotation group, $S_1$ and $S_2$ obey the relations

$$S_1^2 = S_1, \quad S_2^2 = S_2,$$

$$S_1 S_2 + S_2 S_1 + S_2 S_1 = S_2,$$

$$S_1 S_2 + S_2 S_1 + S_2 S_1 = S_2. \quad (3.15)$$

Using (3.14) and (3.15) we have the results

$$G_{1}^{(spin)} G_{2}^{(spin)} = 0, \quad (3.16)$$

$$G_{1}^{(spin)} G_{2}^{(spin)} G_{1}^{(spin)} = 0.$$

As a consequence, we get a closed-form expression for $\Omega(x_1)$; reinstating the constant phase it is
\[ \Omega(x_1) = e^{i\Phi(x_1)} \exp \left[ -\frac{i}{f} x_2 G_a^{(\text{spin})} \right] = e^{i\Phi(x_1)} \left[ 1 - \frac{i}{f} x_2 G_a^{(\text{spin})} - \frac{1}{2f^2} (x_2 G_a^{(\text{spin})})^2 \right] \]

\[ = e^{i\Phi(x_1)} \begin{vmatrix} 1 + \frac{(y^2 - x^2)}{8f^2} & -xy & -x & xy & \frac{(y^2 - x^2)}{8f^2} & \frac{y}{2f} \\ -xy & 1 + \frac{(x^2 - y^2)}{8f^2} & -y & (y^2 - x^2) & -xy & -x \\ \frac{x}{2f} & \frac{y}{2f} & 1 & -\frac{y}{2f} & \frac{x}{2f} & 0 \\ -xy & \frac{(x^2 - y^2)}{8f^2} & -y & 1 + \frac{(y^2 - x^2)}{8f^2} & -xy & -x \\ \frac{x}{2f} & \frac{y}{2f} & 0 & \frac{x}{2f} & \frac{y}{2f} & 1 \end{vmatrix} \] (3.17)

This matrix applied to the column vector made up of the functions \( E_j, B_j \) for the incident wave is expected to yield the column vector of the wave after passage through the lens.

Since we are only interested in exhibiting how the principle expressed by Eq. (3.11) works, we shall retain only the lowest-order term \( x_2 / f \) of the paraxial approximation and neglect the quadratic terms in \( x \) and \( y \) in \( \Omega(x) \), apart from the piece \( e^{i\Phi} \). We also remember from Eq. (3.7) that we can set \( E_1 = B_2, E_2 = -B_1 \) to leading order, and treat \( E_3 \) and \( B_3 \) as being small quantities of first order relative to \( E_a, B_a \). Then after dropping a factor \( e^{-i\Phi} \) common to all the field components, we find that the outgoing \( E', B' \) are related to the incident \( E, B \) by

\[ E'_a(x_1, 0) \approx e^{i\Phi(x_1)} E_a(x_1, 0), \]
\[ B'_a(x_1, 0) \approx e^{i\Phi(x_1)} B_a(x_1, 0), \] (3.18)
\[ E'_j(x_1, 0) \approx e^{i\Phi(x_1)} [E_j(x_1, 0) + (x_2 / f) E_a(x_1, 0)], \]
\[ B'_j(x_1, 0) \approx e^{i\Phi(x_1)} [B_j(x_1, 0) + (x_2 / f) B_a(x_1, 0)]. \]

These formulas show that for a paraxial incident wave, the passage through a lens contributes a small additional axial component which agrees with what one obtains from a more direct calculation based on the condition that the Maxwell equations (2.1c) and (2.1d) must be maintained both before and after the action of the lens. The natural geometrical interpretation of this result will become clear in Sec. V.

To assure ourselves of the correctness of Eqs. (3.18), it is interesting to consider the following simple situation. Let the incident wave be a strictly axial plane wave, so that to the immediate left of the lens we have \( E_1 = B_2, E_2 = -B_1, E_3 = B_3 = 0 \). Then on passage through the lens the wave picks up small nonzero axial components \( E'_3, B'_3 \). These show up vividly in the Poynting vector of the outgoing wave, the components of which are found to be

\[ \text{Re} [\mathbf{E}'(x_1, 0) \times (\mathbf{B}'(x_1, 0))]^* \approx \frac{1}{2} \left( |\mathbf{E}'|^2 + |\mathbf{B}'|^2 \right) (x_1 / f, 1). \] (3.19)

For a converging lens with \( f > 0 \) we see that at each \( x_1 \) to the immediate right of the lens (assuming \( |x_1| \ll f \)) the outgoing Poynting vector points exactly to the focus \((0,0,f)\), which is just what is expected. [If the terms \( x_2E_a, x_2B_a \) in \( E'_3, B'_3 \) in Eqs. (3.18) had been absent, it is clear that the outgoing Poynting vector, like the incoming one, would have been parallel to the system axis at each \( x_1 \).] At the level of the field components we see for example that the electric vector \( \mathbf{E}'(x_1, 0) \) is orthogonal to \((-x_1, f)\) which is the vector leading from \((x_1, 0)\) to the focal point \((0,0,f)\), and similarly for \( \mathbf{B}'(x_1, 0) \). Thus for an incident axial plane wave the lens transformation (3.18) yields an outgoing wave which locally can be described as a set of vector plane waves, all directed to the focal point. This justifies the extension to vector waves of the well-known Debye integral representation for focused fields.12

In principle similar calculations can be carried out for other situations of interest. The identification of the action of various kinds of lenses (in the quadratic phase approximation) with corresponding elements of the group \( SU(2,R) \) when one has axial symmetry [and more generally the group \( Sp(4,R) \)], and even of free propagation according to Eq. (3.8) with an element of this group, goes through with no changes at all compared to the scalar case.

IV. RADIATION GAUGE IN THE FRONT FORM

The description of paraxial solutions of the Maxwell equations and their passage through thin lenses given in the preceding section is physically transparent since the behavior of all six field components \( F_{\mu\nu} \) was specified. However, it is somewhat unwieldy in that one has to contend with six-dimensional matrices, so one may try to give a more economical treatment using a vector potential. For the class of problems one is interested in here, namely, paraxial beams passing through optical systems, one must choose the gauge judiciously, so that the particular generators \( G_a \) in the Poincaré algebra act in a simple way. We show in this section how this is to be done.
To begin with, we recall the Poincaré transformation properties of the radiation gauge potential suited to the instant form. For free fields, this potential is defined by the conditions
\[ A_0(x) = 0, \quad \tilde{\nabla} \cdot \tilde{A}(x) = 0 \]  
so that the usual relations \( F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu \) are in this case
\[ \tilde{E} = -\partial_0 \tilde{A}, \quad \tilde{B} = \tilde{\nabla} \times \tilde{A}. \]  

It is well known that this vector potential transforms simply under space-time translations and spatial rotations, but has a nonlocal behavior under pure Lorentz transformations. In fact, the various generators of the Poincaré group act in this gauge in the following ways\textsuperscript{13}:

\[ P_\mu \tilde{A}(x) = -i \partial_\mu \tilde{A}(x), \]
\[ (J^i)A_k(x) = -i(x^0 \partial_i + x_i \partial_0)A_k(x) = -i[(x^i \partial_0 - x_0 \partial_i) + \{S_\mu, A_\mu(x)\} = -i[(x^i \partial_0 - x_0 \partial_i) + \{S_\mu, A_\mu(x)\}], \]
\[ (K^I)A_k(x) = i(x^0 \partial_I + x_I \partial_0)A_k(x) + \frac{i}{4\pi} \partial_0 \int \frac{d^3x'}{|\tilde{x} - \tilde{x}'|} \cdot \partial_0 A_I(\tilde{x}', x^0). \]

It follows that the nonlocality of the action of \( K_I \) will be present in the combinations \( G_a \) as well, so this gauge is unsuitable for the present situation. We need a gauge which is natural from the front point of view.

We could try setting one of the two components \( A_a \) or \( A_\rho \) equal to zero. From the Lagrangian point of view it is natural to make the choice \( A_\rho = 0 \), but it turns out that this still involves a nonlocal action of \( G_a \). (This will become clear later.) However, this problem does not arise for the choice \( A_a = 0 \). Therefore, for free fields we shall define the vector potential in the front form radiation gauge by the conditions
\[ A_\mu(x) = 0, \quad \tilde{A}_0(x) = A_1(x) = \frac{1}{r} A_r(x), \]
\[ \partial^a A_\mu(x) = 0 \rightarrow \partial_a A_\mu(x) = \partial_\nu A_\nu(x). \]

Then the various components of \( F_{\mu\nu} \) are given by
\[ U_a = \partial_a A_a, \]
\[ E_3 = -\partial_0 A_\tau = -\partial_0 A_3, \]
\[ B_3 = \epsilon_{ab} \partial_a A_b, \]
\[ V_\rho = \partial_\rho A_\tau - \partial_\tau A_\rho. \]

One easily checks that the Maxwell equations in the front form, (2.10), behave in the following way when these expressions are put in: The equation of motion (2.10b) and the constraints (2.10d), (2.10e) are identically obeyed; the equation of motion (2.10a) leads to the wave equation for \( A_\tau \); the equations of motion (2.10c) as well as the constraints (2.10f) lead to the wave equations for \( A_a \).

The forms of the generators of the Poincaré group, suitable for application to this vector potential, can be obtained in a straightforward way. For those infinitesimal transformations which preserve the conditions (4.4) when we naively transform \( A_\mu \) as though it were a four-vector field, there is no difficulty at all. In other cases, we find that conditions (4.4) can be restored by a suitable gauge transformation after we have first transformed \( A_\mu \) as a four-vector. In this way we get for the generators acting on the column vector
\[
\begin{bmatrix}
A_1 \\
A_2 \\
A_3 \\
A_r
\end{bmatrix}
\]
the following expressions:
\[
\begin{align}
P_\mu &= -i \partial_\mu, \quad M = \frac{i}{2}(P^0 + P^3) = i \partial_\nu, \quad H = P^0 - P^3 = i \partial_\nu, \\
J_3 &= -i \epsilon_{ab} x_a \partial_b + S_3, \\
G_a &= M_{x_a} - \tau P_a + G_a^{(\text{spin})}, \quad G_1^{(\text{spin})} = \begin{bmatrix} 0 & 0 & 0 \\
0 & 0 & 0 \\
i & 0 & 0 \end{bmatrix}, \quad G_2^{(\text{spin})} = \begin{bmatrix} 0 & 0 & 0 \\
0 & 0 & 0 \\
i & 0 & 0 \end{bmatrix}, \\
K_3 &= \tau H - \sigma M + \begin{bmatrix} 0 & 0 & 0 \\
0 & 0 & 0 \\
i & 0 & 0 \end{bmatrix}, \\
(K_1 + J_2) &= \begin{bmatrix} A_1(\sigma x_1; \tau) \\
A_2(\sigma x_1; \tau) \\
A_3(\sigma x_1; \tau) \end{bmatrix} = \begin{bmatrix} H_{x_1} - \sigma P_1 + \begin{bmatrix} 0 & 0 & 0 \\
0 & 0 & 0 \\
i & 0 & 0 \end{bmatrix} A_1 \\
0 & A_2 - \frac{i}{\pi} \frac{1}{\partial_0} \int d^2x'_1 \ln |x_1 - x'_1| \partial_\tau A_1(\sigma x'_1; \tau) \\
0 & A_3 \end{bmatrix}, \\
(K_2 - J_1) &= \begin{bmatrix} A_1(\sigma x_1; \tau) \\
A_2(\sigma x_1; \tau) \\
A_3(\sigma x_1; \tau) \end{bmatrix} = \begin{bmatrix} H_{x_2} - \sigma P_2 + \begin{bmatrix} 0 & 0 & 0 \\
0 & 0 & 0 \\
i & 0 & 0 \end{bmatrix} A_1 \\
0 & A_2 - \frac{i}{\pi} \frac{1}{\partial_0} \int d^2x'_1 \ln |x_1 - x'_1| \partial_\tau A_2(\sigma x'_1; \tau) \\
0 & A_3 \end{bmatrix}. 
\end{align}
\]
In comparison with the situation described by Eq. (4.3) and pertaining to the instant form, we notice two interesting points: (i) out of the ten generators only two have a nonlocal action in the front form radiation gauge; (ii) this nonlocality is with respect to two of the "spatial" variables $x_a$ in the front alone, and not with respect to $\sigma$. From (4.6c) and (4.6e) it is also clear that if we had chosen the gauge $A_\tau=0$ rather than $A_\alpha=0$, which amounts to interchanging the roles of $\sigma$ and $\tau$, $G_\sigma$ would have had a nonlocal action but $K_1+J_2$ and $K_1-J_2$ would become simple.

We want now to set up a vector potential that will yield the quasihenochromatic paraxial solution \([3.4] \text{ and } [3.5]\) of the Maxwell equations, and are interested only in the region (3.3) where it is effectively henchromatic. This potential can be easily guessed from Eqs. (4.5) and it is

$$A_\sigma(\sigma;x_1;\tau) = \frac{i}{\mathcal{H}_0} U_\alpha(\sigma;x_1;\tau),$$

(4.7)

$$A_\sigma(\sigma;x_1;\tau) = -\frac{i}{\mathcal{H}_0} \partial_\sigma U_\alpha(\sigma;x_1;\tau).$$

One can check that the gauge condition (4.4) as well as all of Eqs. (4.5) are obeyed. We see that $A_\tau$ is smaller than $A_\alpha$ by 1 order of magnitude in the small quantity $\Delta k/\mathcal{H}_0$.

$$A_\tau = \frac{\Delta k}{\mathcal{H}_0} A_\alpha,$$

(4.8)

which must be compared to the relationships (3.6) among the field components. From a physical point of view, because of Eq. (3.7) we can say that up to and including first-order terms in $\Delta k/\mathcal{H}_0$ the vector potential coincides with the electric field:

$$A_\alpha \approx \frac{-i}{\mathcal{H}_0} E_\alpha, \quad A_\tau \approx \frac{-i}{\mathcal{H}_0} E_\tau.$$

(4.9)

Of course, it obeys the free propagation equation (3.8) just like the field components.

In this formalism the lens transformation matrix is three dimensional and its computation is algebraically even simpler than in the formalism of the preceding section working with field components. This is because the matrix terms in $G_\sigma$ of Eq. (4.6c) obey

$$G_1^{(\text{spin})} = G_1^{(\text{spin})}, \quad G_2^{(\text{spin})} = G_2^{(\text{spin})}, \quad G_1^{(\text{spin})} = G_1^{(\text{spin})}.$$

(4.10)

$$= (G_2^{(\text{spin})})^2 = 0.$$

We therefore expect that in the paraxial approximation to leading order the effect of a thin circular lens of focal length $f$ on the vector potential of an incident henchromatic paraxial wave is given by the matrix

$$\vec{\Omega}(x_1) = \exp \left[ i \mathcal{H}_0 \Delta_0 - \frac{i}{\mathcal{H}_0} \mathcal{H}_0 \left( x_1 + \frac{1}{\mathcal{H}_0} (G_1^{(\text{spin})})^2 \right) \right],$$

$$= \exp \left[ i \left( G_1^{(\text{spin})} - x_1/f G_\alpha^{(\text{spin})} \right) \right] = e^{i q x_1} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ x/f & y/f & 1 \end{bmatrix}. $$

(4.11)

Therefore, the outgoing vector potential is related to the incident one by

$$A_\alpha = e^{i q A_\alpha}, \quad A_\tau = e^{i q \left( A_\tau + x_1 A_\alpha/f \right)}.$$

(4.12)

It is easy to verify that the gauge condition (4.4) is maintained by this transformation, and when we take account of (4.9) we see that we have recovered Eqs. (3.18) for the components of the electric field. To leading order one can also confirm that the changes in $B_0, B_3$ contained in (3.18) are properly reproduced; making use of Eqs. (3.7) and (4.9), we have for $B_3$:

$$B_3 = \epsilon_{\alpha \beta \gamma} \partial_\alpha B_\beta \approx \epsilon_{\alpha \beta \gamma} \partial_\alpha \left[ e^{i q \left( x_1 A_\alpha/f \right)} A_\beta \right]$$

$$= e^{i q} \epsilon_{\alpha \beta \gamma} \left( \partial_\alpha A_\beta - i \mathcal{H}_0 \left( x_1 A_\alpha/f \right) x_1 A_\beta \right)$$

$$= e^{i q} \left[ B_3 + \left( x_1 A_\alpha/f \right) B_\alpha \right].$$

(4.13)

Thus, to leading order, the six-dimensional lens transformation matrix of Eq. (3.17) and the simpler three-dimensional one of Eq. (4.11) give mutually consistent results.

V. PENCILS OF ELECTROMAGNETIC RAYS

IN PARAXIAL OPTICS

The second-order coherence properties of a general statistical state of the Maxwell field are described by suitable correlation tensors\(^{15}\) that generalize the two-point correlation function of the scalar treatment. These tensors could be defined in terms of the components of the electric and magnetic field vectors or, more simply, in terms of the vector potential. We shall work with the latter and shall briefly indicate how the concept of generalized pencils of rays\(^{5}\) is set up for vector waves in the paraxial limit.

Let the subscripts $\alpha, \beta, \ldots$, run over the values $1, 2, \tau$. Consider an ensemble of quasihenochromatic paraxial waves with characteristic parameters $\mathcal{H}_0, \Delta k, \Delta \mathcal{H}_0$. In the space-time region (3.3) where it is effectively henchromatic, the representative vector potential in the front form radiation gauge can be written as

$$A_\alpha(\sigma;x_1;\tau) \approx e^{-i q \sigma} \mathcal{Q}_\alpha x_1;\tau,$$

(5.1)

and we remember that $\mathcal{Q}_\beta$ is smaller than $\mathcal{Q}_\alpha$ by a factor $\Delta k/\mathcal{H}_0$. For any two points on the same front we define the correlation tensor $\Gamma$ as

$$\Gamma_{\alpha \beta}(\sigma_1, x_1; x_2; \tau_2) = \left\langle \left[ A_\alpha(\sigma_1; x_1; \tau_1) \right]^* A_\beta(\sigma_2; x_2; \tau_2) \right\rangle$$

$$= e^{i q (\sigma_1 - \sigma_2) \mathcal{H}_0} \left\langle \mathcal{Q}_\alpha^\dagger x_1; \tau_1 \mathcal{Q}_\beta x_2; \tau_2 \right\rangle,$$

(5.2)

$$\Gamma^{(0)}(\sigma_1, x_1; x_2; \tau_2) = \left\langle \left[ \mathcal{Q}_\alpha^\dagger x_1; \tau_1 \right]^* \mathcal{Q}_\beta x_2; \tau_2 \right\rangle.$$

The angular brackets denote an average over the ensemble. The leading elements of this matrix are $\Gamma^{(0)}_{\alpha \beta}$, the elements $\Gamma^{(0)}_{\alpha \beta}$ and $\Gamma^{(0)}_{\beta \beta}$ are smaller by a factor $\Delta k/\mathcal{H}_0$, while the last element $\Gamma^{(0)}_{\beta \beta}$, being smaller by $(\Delta k/\mathcal{H}_0)^2$, will be neglected. The Wolf matrix of generalized rays of light is now defined as a Wigner-Moyal transform of $\Gamma^{(0)}$.\(^{5}\)
\[
W_{ab}(x_i; p_1; \tau) = (2\pi)^{-2} \int d^2 \xi e^{i p_1 \xi} \Gamma_{ab}^{(0)}(x_1 + \frac{i}{\Delta k} \xi) x_1 - \frac{i}{\Delta k} \xi; \tau).
\]  
(5.3)

This is a Hermitian, but not pointwise positive definite, matrix. Since the paraxial condition is assumed to hold over the entire ensemble, it is easy to see that \(W_{ab}(x_i; p_1; \tau)\) is nonzero only for \(p_1\) in the range \(|p_1| \leq \Delta k \ll \mathcal{M}_0\). Thus, we can interpret \(W_{ab}(x_i; p_1; \tau)\) as representing in matrix form the transverse intensity of the paraxially polarized generalized rays of light at the point \(x_1\) in the front \(\tau\), traveling in the transverse direction \(p_1\). As in the scalar case, this intensity is guaranteed to be real but may not be positive. The elements \(W_{ab}(x_i; p_1; \tau)\) describe the correlation at the point \(x_1\), between the transverse and the longitudinal rays having a common direction \(p_1\). \(W_{ab}(x_i; p_1; \tau)\) must be interpreted as the intensity of generalized longitudinal rays, but since it is of order \((\Delta k / \mathcal{M}_0)^2\), we neglect it in interpreting the matrix \(W\). In this way, we of course make use of Eqs. (4.9).

The gauge condition (4.4) on the vector potential leads to a condition on the matrix \(W\) which can be expressed as a determinant of \(W_{ab}\) in terms of \(W_{ab}\):

\[
W_{ab}(x_i; p_1; \tau) = \frac{i}{\mathcal{M}_0} \frac{1}{2} \frac{\partial}{\partial \xi_b} + l p_b \right] W_{ab}(x_i; p_1; \tau).
\]  
(5.4)

This equation lends itself to the following interpretation. For a uniform beam for which we can neglect the variation with respect to \(x_1\), except at the very edges, Eq. (5.4) states that the polarization is perpendicular to the paraxial ray direction given by \(p = \mathcal{M}_0 \xi_1\). Near the edges of the beam, the polarization is no longer strictly transverse, a result already known from previous work. \(^3\) The free propagation law for \(W\) is as simple as in the scalar case, because Eq. (3.8) applies to the vector potential also:

\[
W_{ab}(x_i; p_1; \tau) = W_{ab}(x_i - \tau \xi_1 / \mathcal{M}_0 p_1; 0).
\]  
(5.5)

This means that in free space generalized rays travel in straight lines with unchanging polarization properties, in the paraxial approximation.

Finally, we see how the matrix \(W\) is changed by a thin circular lens placed centrally and normally on the axis at \(x^3 = 0\). The effect on the "reduced" vector potential \(\mathcal{A}_a\) is given by Eqs. (4.11) and (4.12) and is

\[
\mathcal{A}_a(x_i; 0) = e^{iq(x_1)} T_{ab}(x_1) \mathcal{A}_b(x_i; 0),
\]

\[
T_{ab}(x_1) = \delta_{ab} + \delta_{ac} \delta_{b} \delta_{c} / f.
\]  
(5.6)

It follows that the change produced in the correlation tensor \(\Gamma^{(0)}\) is, in matrix form,

\[
\Gamma^{(0)}(x_1; x_2; 0) = e^{i(q(x_1) - q(x_2))} [T(x_1)]^n \times \Gamma^{(0)}(x_1; x_2; 0) [T(x_2)]^n
\]  
(5.7)

where the asterisk and the tilde denote complex conjugation and the transpose, respectively. From here we can easily calculate the change in \(W\) and find

\[
W_{ab}(x_i; p_1; 0) = W_{ab} \left( x_i + \mathcal{M}_0 / \Delta k x_1; 0 \right),
\]

\[
W_{ab}(x_i; p_1; 0) = W_{ab} \left( x_i + \frac{\mathcal{M}_0}{\Delta k} x_1; 0 \right) + \frac{1}{f} \left( \delta_{ab} \right) \frac{\partial}{\partial \xi_b} \right] W_{ab} \left( x_i + \frac{\mathcal{M}_0}{\Delta k} x_1; 0 \right).
\]  
(5.8)

We see, as in the scalar case described in I, that the generalized rays are bent by the lens in a simple geometrical way. The lens action given above preserves the condition (5.4) and the gauge condition on the vector potential. Since Eq. (5.4) guarantees that the polarization is perpendicular to the paraxial direction, it follows that the lens action given by Eqs. (5.8) is as such to preserve this condition.

VI. CONCLUDING REMARKS

In the two papers of this series we have developed a general formalism which, we believe, is ideally suited for analysis of all paraxial-wave optical problems. The use of relativistic ideas has led us in a natural way to a classification of the space-time coordinates as well as of field components of the Maxwell field according to their importance in terms of the basic parameters \(\Delta k / \mathcal{M}_0\) of a paraxial beam.
transformation matrix. In both cases above, $G_s(0)/M$ and the transverse momenta $P_x$ form two canonically conjugate pairs but they are reducible in the operator sense. This rule has led to correct and consistent results, and it is natural to search for a simple explanation of this fact. This is actually not hard to find. The essential physical point is that—whether we speak in terms of the field strengths $\vec{E}, \vec{B}$ or the vector potential $A$—each transverse component propagates through every ideal optical system as though it were a scalar wave, while the axial components propagate almost as if they were also a scalar wave.\(^7\)

The departure from such behavior for these latter components is just enough to ensure that the constraint equations (2.1c) and (2.1d) on $\vec{E}, \vec{B}$ or the gauge condition (4.4) on $A$ are maintained both before and after the encounter with the lens. Now for paraxial situations, if we make use of Eqs. (4.9) and neglect terms of second order in $\Delta k/\Delta t$, we find

$$
\vec{\nabla} \cdot \vec{E} = \partial_x E_x + \left( \frac{1}{i} \partial_t - \partial_\phi \right) E_\phi \approx \partial_x E_x - \partial_\phi E_\phi \\
\approx i \times \vec{A}(\partial_x A_y - \partial_y A_x),
$$

(6.2)

while $\vec{\nabla} \cdot \vec{B}$ vanishes identically when $B$ is expressed in terms of $A$. So in the front formalism both the gauge condition (4.4) on $A$ and the Maxwell equation $\vec{\nabla} \cdot \vec{E} = 0$ are constraint conditions since they do not involve derivatives of any field quantities with respect to $\tau$. Now we pointed out in I that for the scalar wave equation a solution remains a solution if we apply any function $F(M_{\mu\nu} P_{\rho})$ of the Poincaré generators to it, provided $F$ has no explicit dependence on space-time variables. An analogous statement is true for vector waves. Any function of the six-dimensional matrix generators (2.15) can be applied to a column vector made up of an $\vec{E}$ and a $\vec{B}$ obeying Maxwell's equations, and the result will be another solution; or we can apply a function of the three-dimensional matrix generators (4.6) to a vector potential $(A_x, A_y)$ obeying the gauge condition (4.4) and the wave equation, and the result will also obey both. This is a consequence of the linearity and the Poincaré invariance of the respective equations. While the function $F$ of the generators must not carry any explicit $\tau$ dependence, the generators themselves, or at least some of them like $G_s(\tau)$, may carry explicit dependences on $\tau$. But if one seeks only to maintain the constraint relation $\vec{\nabla} \cdot \vec{E} = 0$, then one can relax the conditions mentioned above and apply a function of $G_s(0)/M$, rather than $G_s(\tau)/M$, to fields obeying this constraint, and the constraint will be maintained.

The formal similarity of paraxial problems to a nonrelativistic quantum-mechanical "particle" in two dimensions persists in going from the scalar theory to Maxwell's equations.\(^8\) If we use the approach based on the vector potential, we can say that the particle can have "helicity" $\pm 1$ or 0. But while in the scalar theory every thin lens imparted a harmonic impulse which is just a phase change and so a unitary transformation, with the vector potential the transformation matrix, for example in Eq. (4.11), is not unitary. Nevertheless it is would be worthwhile computing the transformation matrices for various configurations of interest. It would also be interesting to examine the detailed behavior of generalized pencils of light endowed with polarization, in situations where the optical system has a nontrivial effect on the state of polarization. We hope to come back to these questions and to other applications of our formalism elsewhere.
